Guruswami-Sudan Decoding of Elliptic Codes Through Module Basis Reduction

Yunqi Wan, Member, IEEE, Li Chen, Senior Member, IEEE, and Fangguo Zhang

Abstract—This paper proposes the Guruswami-Sudan (GS) list decoding algorithm for one-point elliptic codes, in which the interpolation is realized by the module basis reduction (BR). Elliptic codes are a kind of algebraic-geometric (AG) codes with a genus of one. Over the same finite field, they have a greater codeword length than Reed-Solomon (RS) codes, capable of correcting more errors. The GS decoding consists of interpolation and root-finding, while the former that determines the interpolation polynomial Q(x,y,z) dominates the decoding complexity. By defining the Lagrange interpolation function over an elliptic function field, a basis of the interpolation module can be constructed. The desired Gröbner basis that contains Q(x,y,z) can be determined by reducing the constructed basis. This is namely the BR interpolation and it requires less finite field arithmetic operations than the conventional Kötter’s interpolation, facilitating the GS decoding. Re-encoding transform (ReT) is further introduced to facilitate the BR interpolation. This work also shows that both the BR interpolation and its ReT variant will have a lower complexity as the code rate k/n increases, where n and k are the length and dimension of the code, respectively. Our numerical results demonstrate the complexity advantage of the BR interpolation over Kötter’s interpolation, and the performance advantage of elliptic codes over RS codes.

Index Terms—Algebraic-geometric codes, basis reduction, elliptic codes, Gröbner basis, interpolation, list decoding.

I. INTRODUCTION

ALGEBRAIC-GEOMETRIC (AG) codes were introduced by Goppa [1]. They are constructed based on algebraic curves over a finite field. Reed-Solomon (RS) codes can be seen as a special class of AG codes that are constructed from a straight line. Hence, the length of an RS code cannot exceed the size of the finite field, limiting the code’s minimum Hamming distance and the number of errors that can be corrected by the code. However, there exist other algebraic curves on which the number of rational points can be greater than the size of the field. This gives AG codes the codeword length and distance advantages over RS codes. Therefore, AG codes have the potential to replace RS codes in communication and storage systems. They can also be applied in cryptography and complexity theory. For an AG code, its minimum Hamming distance would be lower bounded by the designed distance $d^*$, where $d^* = n - k - g + 1$, and n and k are the length and dimension of the code, respectively, and g is the genus of the curve. Note that for RS codes, $g = 0$ and they become the maximum distance separable (MDS) codes. For AG codes, $g > 0$, they are usually not MDS codes. In the AG family, Hermitian codes have a large codeword length and Hermitian curves also exhibit rich structural symmetries which are beneficial for coding practice. However, their codeword length comes at the cost of a large genus penalty. For elliptic codes, $g = 1$. They are either MDS or almost MDS codes, yielding a good tradeoff between its codeword length and distance property.

Decoding of AG codes can be categorized into the syndrome based approach and the interpolation based approach. The syndrome based decoding algorithms yield a unique decoded message. Syndromes are used to determine the error locations and their magnitudes. Driencourt [2] presented a decoding algorithm for elliptic codes, which is the early syndrome based decoding for the code. It can correct at most $\left\lfloor \frac{d^* - 1}{2} \right\rfloor$ errors. Following Peterson’s algorithm [3] for decoding BCH codes, Justesen et al. [4] proposed a decoding algorithm for a class of AG codes based on plane curves. Skorobogatov and Vladut [5] further generalized the algorithm to decode AG codes that are constructed from an arbitrary algebraic curve, presenting an algorithm that can correct at most $\left\lfloor \frac{d^* - 1}{2} \right\rfloor$ errors. By introducing majority voting for the unknown syndromes, Feng and Rao [6] proposed a decoding algorithm for one-point AG codes that can correct up to $\left\lfloor \frac{d^* - 1}{2} \right\rfloor$ errors. Duursma [7] further extended the algorithm to decode arbitrary AG codes. The original Berlekamp-Massey (BM) algorithm on univariate linear recurring relation was generalized by Sakata [8] to the multivariate domain for decoding AG codes, which is called the BMS algorithm. Based on the majority voting and the BMS algorithm, Sakata et al. [9] presented a more efficient decoding algorithm for AG codes, with a complexity of $O(n^2/3)$. Its performance in decoding Hermitian codes over wireless channels has been later investigated by Johnston and Cerracosta [10], shedding lights on their practical applications. Based on the shift-register

synthesis techniques, Schmidt et al. [11] proposed power decoding for low rate RS codes, which can correct more than \( \lfloor \frac{d - 1}{2} \rfloor \) errors. Nielsen and Beelen [12] further generalized it to decode low rate Hermitian codes.

The interpolation based algebraic list decoding has an error-correction capability beyond \( \lfloor \frac{d - 1}{2} \rfloor \). Sudan [13] first proposed the decoding concept for low rate RS codes. Shokrollahi and Wasserman further generalized it for low rate AG codes [14]. By constructing a curve that passes through all interpolation points with a certain multiplicity, Guruswami and Sudan [15] later improved it to decode all rate RS and AG codes, namely, the Guruswami-Sudan (GS) algorithm. It can correct up to \( n - \lfloor \sqrt{n(n-d^2)} \rfloor - 1 \) errors. The GS algorithm consists of interpolation and root-finding, where the former dominates the decoding complexity. Interpolation constructs a minimum polynomial that has a zero of multiplicity \( m \) over a set of interpolation points. This construction can be realized by Kötter’s iterative polynomial construction [16]. The decoded message can be obtained by finding roots of the interpolation polynomial. Soft-decision algebraic list decoding of RS codes was later proposed by Kötter and Vardy [17]. To facilitate Kötter’s interpolation, re-encoding transform (ReT) has been introduced [18]. By defining the zero basis for each affine point, Hohenlohe and Nielsen [19] presented a mathematical framework for GS decoding of Hermitian codes, including Kötter’s interpolation as the key decoding step. Under Kötter’s interpolation paradigm, soft-decision algebraic list decoding of Hermitian codes was later proposed by Chen et al. [20]. Recently, GS decoding of elliptic codes using Kötter’s interpolation was proposed by the authors [21].

The other interpolation technique is from the perspective of the Gröbner basis of a module [22]. One may form the basis of a module that contains polynomials with the interpolation multiplicity and degree constraints. The basis will be further reduced, yielding the Gröbner basis that contains the desired interpolation polynomial. This is called the basis reduction (BR) interpolation [23]. In comparison with Kötter’s interpolation for decoding AG codes, it not only requires less computation, but also eliminates the need of pre-computing the zero basis for each affine point and the corresponding coefficients [24], [25]. Lee and O’Sullivan proposed the GS decoding of Hermitian codes using the BR interpolation [26]. They later generalized the interpolation technique for soft-decision algebraic list decoding of Hermitian codes [27]. Both the Lee-O’Sullivan algorithm [26] and the Mulders-Storjohann (MS) algorithm [28] can be used to reduce the module basis into a Gröbner basis. Other facilitating techniques for the basis reduction process include the Alekhnovich algorithm [29] and the Giorgi-Jannerod-Villard (GJV) algorithm [30]. Applying the former, Beelen and Brander reduced the complexity in finding the interpolation polynomial for a class of AG codes [31]. Applying the latter, Nielsen and Beelen also presented a fast GS decoding algorithm for Hermitian codes [12].

This paper introduces the GS decoding of one-point elliptic codes using the BR interpolation. In order to construct the basis of a module, the Lagrange interpolation functions over the elliptic function field are introduced. They lead to the formulation of the module basis generators. The constructed basis will be reduced to the desired Gröbner basis by Lee-O’Sullivan’s algorithm [26], from which the interpolation polynomial \( Q(x, y, z) \) can be obtained. In order to further reduce the interpolation complexity, the ReT is introduced for the decoding. It transforms the received word into containing at least \( \varepsilon \) zero symbols, where \( \varepsilon = k - 1 \) or \( k - 2 \). This results in basis generators of the module sharing a common factor which can be removed to reduce the basis reduction complexity. This work shows that the BR interpolation exhibits a complexity of \( O(l^3 m^2 n(n-k)) \), where \( m \) is the interpolation multiplicity and \( l \) is the maximum decoding output list size. The ReT can help reduce it to \( O(l^3 m^2 (n-k)^2) \). Hence, both the BR interpolation and its ReT variant will have a lower complexity as the code rate \( k/n \) increases. This is in contrast to Kötter’s interpolation whose complexity grows with the rate. This work also discusses the impact of using the Alekhnovich algorithm and the GJV algorithm for the basis reduction process. They are capable to reduce the complexity into quasi-linear in \( n \). However, we show that such complexity advantage can only be realized when \( n \) is so large that beyond the current practical interest. Finally, our numerical results demonstrate the complexity advantage of the BR interpolation over Kötter’s interpolation in decoding elliptic codes, as well as the performance advantage of elliptic codes over RS codes.

II. BACKGROUND KNOWLEDGE

A. Elliptic Codes

Let \( F_q \) denote the finite field of size \( q \). An elliptic curve \( E \) in homogeneous coordinates over \( F_q \) is defined by a nonsingular Weierstrass equation

\[
Y^2 + a_1 XY Z + a_3 Y Z^2 = X^3 + a_2 X^2 Z + a_4 X Z^2 + a_6 Z^3,
\]

where \( a_1, a_2, a_3, a_4, a_6 \in F_q \). On \( E \), there exists the point of infinity \( P_{\infty} = (0, 1, 0) \). With \( Z = 1 \), curve

\[
Y^2 + a_1 X Y + a_3 Y = X^3 + a_2 X^2 + a_4 X + a_6
\]

becomes an affine component, which is called the affine curve. Points on the curve are called affine points. They are denoted as \( P_i = (x_i, y_i) \). Let \( E(F_q) \) denote the set of \( F_q \)-rational points on \( E \) as \( E(F_q) = \{ P_i \} | \{ P_{\infty} \} \). They form an additive Abelian group based on the “chord-and-tangent” rule with \( P_{\infty} \) as the identity element [32]. Let \( -P_i \) denote the inverse of \( P_i \). \( P_i \) and \( -P_i \) are the only affine points on \( E \) with the same \( x \)-coordinate. For any \( P_i \), there exists a smallest nonnegative integer \( \delta \) such that \( \delta P_i = P_{\infty} \), where \( \delta \) is the order of \( P_i \). It divides the order of \( E(F_q) \). Coordinate ring of \( E \) is an integral domain, i.e.,

\[
\mathcal{R} = F_q[X, Y]/ < Y^2 + a_1 X Y + a_3 Y - X^3 - a_2 X^2 - a_4 X - a_6 > = F_q[x, y],
\]

where \( x \) and \( y \) denote the residue classes of \( X \) and \( Y \), respectively. Elements of \( \mathcal{R} \) are bivariate polynomials with
y-degree less than two. Based on E, its function field $\mathbb{F}_q(E)$ would be the quotient field of $\mathcal{R}$.

Given $h \in \mathbb{F}_q(E)$, its order at a rational point $P$ is $v_P(h)$, where $v_P(\cdot)$ denotes the valuation of $h$ at $P$ [32]. There exists a function $\Lambda$ which is called the local parameter of $P$. It enables $v_P(\Lambda) = 1$ and $h = \Lambda^{v_P(h)}h'$, where $v_P(h') = 0$.

If $v_P(h) \geq 0$, $h$ has a zero of order $v_P(h)$ at $P$. Otherwise, it has a pole of order $-v_P(h)$ at $P$. For elliptic curves, $-v_P(\infty) = 2$, $-v_P(y) = 3$ and $-v_P(x^2y^3) = 2\lambda + 3\gamma$.

Definition 1 ([32]): For each point $P$, we define a formal symbol $[P]$. Let $n_P$ denote an integer that corresponds to $P$, $D = \sum_{P \in \mathcal{E}(\mathcal{R})} n_P [P]$ is a divisor of $E$. It has a degree of $\deg(D) = \sum_{P \in \mathcal{E}(\mathcal{R})} n_P$ and a sum of $\sum(D) = \sum_{P \in \mathcal{E}(\mathcal{R})} n_P [P]$.

Definition 2 ([32]): If $h \in \mathbb{F}_q(E)$ and $h \neq 0$, the divisor of $h$ is defined as $\text{div}(h) = \sum_{P \in \mathcal{E}(\mathcal{R})} v_P(h)[P]$. $\text{div}(h)$ is also called the principal divisor of $E$.

For any divisor $D$, let $\mathcal{L}(D)$ denote the Riemann-Roch space defined by $D$. Therefore, $\mathcal{L}(u[P_\infty]) = \{h \in \mathbb{F}_q(E) | \text{div}(h) + u[P_\infty] \geq 0 \} \cup \{0\}$ has a basis consisting of

$$\{\phi_a = x^\lambda y^\gamma | 2\lambda + 3\gamma \geq u, a, \lambda, \in \mathbb{N}, \gamma \in \{0, 1\}\}$$

which satisfies $-v_P(\phi_a) < -v_P(\phi_{a+1})$, where “$\geq$” indicates that the coefficients of $\text{div}(h) + u[P_\infty]$ are nonnegative and $\mathbb{N}$ denotes the set of nonnegative integers. The basis of $D$ is called the pole basis. Consequently, $\mathcal{R} = \bigcup_{D=\sum_{P \in \mathcal{E}(\mathcal{R})} n_P [P]} \mathcal{L}(u[P_\infty])$.

If $h \in \mathcal{R}$, it can be written as $h = \sum_{P \in \mathcal{E}(\mathcal{R})} \zeta_a \phi_a$, where $\zeta_a \in \mathbb{F}_q$ and $-v_P(h) = \max(-v_P(\phi_a) | \zeta_a \neq 0)$.

Given $n$ distinct affine points $P_0, P_1, \ldots, P_{n-1}$, a divisor $G = \sum_{i=0}^{n-1} [P_i]$ can be formed. Let $f \in \mathcal{L}(k[P_\infty])$ denote the message polynomial that is

$$f(x, y) = f_0 \phi_0 + f_1 \phi_1 + \cdots + f_{k-1} \phi_{k-1},$$

where $f_0, f_1, \ldots, f_{k-1} \in \mathbb{F}_q$ are the message symbols. Based on $E$, an $(n, k)$ one-point elliptic code can be generated by the following evaluation

$$C_E(G, k[P_\infty]) = \{(f(P_0), f(P_1), \ldots, f(P_{n-1})) | \forall f \in \mathcal{L}(k[P_\infty])\},$$

where codeword $\zeta = (\zeta_0, \zeta_1, \ldots, \zeta_{n-1}) = (f(P_0), f(P_1), \ldots, f(P_{n-1})) \in \mathbb{F}_q^n$. Its minimum Hamming distance $d \geq d^* = n - k$.

The above description shows that the number of affine points on the curve defines the length of the code. Based on the Hasse-Weil bound [34], the maximum number of rational points on a curve defined over $\mathbb{F}_q$ is $q + \frac{1}{2}\sqrt{q} + 1$, where $q$ is the genus of a nonsingular curve $b$ and $g = \frac{(b-1)(b-2)}{2}$. For elliptic curves, $b = 3$, $g = 1$ and $|E(\mathbb{F}_q)| \leq q + \frac{1}{2}\sqrt{q} + 1$. It should be pointed that the existence of affine points of order two will make the following interpolation module basis construction cumbersome. Therefore, when designing an elliptic code, the curve coefficients $a_1, a_2, a_3, a_4, a_6$ should be chosen appropriately, so that the curve does not have affine points of order two, but the number of rational points can still reach the Hasse-Weil bound. Therefore, in this paper, the constructed elliptic codes have length $q + [2\sqrt{q}]$.

B. The GS Decoding

Let $\mathcal{R}[z]$ denote the polynomial ring defined over $\mathcal{R}$ and $\mathcal{R}[z]_l = \{Q \in \mathcal{R}[z] | \deg_z Q \leq l\}$. Given $z = (r_0, r_1, \ldots, r_{n-1}) \in \mathbb{F}_q^n$ as a received word, it can be seen as a variant of $\mathcal{E}$ i.e., $z = \mathcal{E} + \mathcal{E}$ where $\mathcal{E} \in \mathbb{F}_q^n$ is an error vector.

The GS decoding consists of interpolation and root-finding. First, let us define $P$ as the set of $n$ interpolation points

$$P = \{(P_0, r_0), (P_1, r_1), \ldots, (P_{n-1}, r_{n-1})\}.$$

Interpolation: Given a received word $z$ and the decoding parameters $m$ and $l$, construct a nonzero minimum polynomial $Q(x, y, z) = \sum_{i=0}^{l} \psi_i (x, y) z^i \in \mathcal{R}[z]$, it interpolates all points of $P$ with a multiplicity of $m$.

Root-finding: Given the interpolation polynomial $Q(x, y, z)$, find all $z$-roots in the form of $f(x, y)$.

A polynomial $Q \in \mathcal{R}[z]$ can be written as

$$Q = \sum_{a \in \mathbb{F}_q} \sum_{b \leq l} Q_{ab} \phi_a z^b,$$

where $Q_{ab} \in \mathbb{F}_q$. For each affine point $P_i$, there exists a basis $\{\psi_{P_i,0}, \psi_{P_i,1}, \ldots, \psi_{P_i,m-1}\}$ of $\mathcal{L}(u[P_\infty])$ such that $\psi_{P_i,0}(x, y) = 0$ and $\psi_{P_i,1}(x, y) = 1$. Functions of this basis have an increasing zero order w.r.t. $P_i$ [19]. The complexity of computing the basis is $O(u^2)$. Given a pole basis monomial $\phi_a$, we have

$$\phi_a = \sum_{\mu \in \mathbb{F}_q} \xi_{a, P_i, \mu} \psi_{P_i, \mu},$$

where $\xi_{a, P_i, \mu} \in \mathbb{F}_q$ is the corresponding coefficient between $\phi_a$ and $\psi_{P_i, \mu}$ [19, 24]. Since

$$z^b = (z - r_1 + r_i)^b = \sum_{\nu \in \mathbb{F}_q} \binom{b}{\nu} r_1^{b-\nu} (z - r_i)^\nu,$$

together with (9) and (10), $Q$ can be written as

$$Q = \sum_{a \in \mathbb{F}_q} \sum_{b \leq l} \sum_{\mu \in \mathbb{F}_q} \xi_{a, P_i, \mu} \psi_{P_i, \mu} \sum_{\nu \in \mathbb{F}_q} \binom{b}{\nu} r_1^{b-\nu} (z - r_i)^\nu \psi_{P_i, \mu} (z - r_i)^\nu.$$

We denote

$$D^{(P_i, r_i)}(Q) = \sum_{a \in \mathbb{F}_q} \sum_{b \leq l} \sum_{\mu \in \mathbb{F}_q} \xi_{a, P_i, \mu} \psi_{P_i, \mu} \sum_{\nu \in \mathbb{F}_q} \binom{b}{\nu} r_1^{b-\nu} \psi_{P_i, \mu} (z - r_i)^\nu.$$
as the $(\mu, \nu)$-Hasse derivative evaluation of $Q$ at $(P_i, r_i)$. If $Q(P_i, r_i) = 0$, $Q$ interpolates $(P_i, r_i)$. Furthermore, if $D_{\mu, \nu}^{(P_i, r_i)}(Q) = 0$, $\forall \mu + \nu < m$, $Q$ interpolates the point with a zero of multiplicity $m$. Eq. (12) defines the interpolation constraints for $Q$. Since there are $\binom{m+1}{2}$ pairs of $(\mu, \nu)$ that satisfy $\mu + \nu < m$, interpolating all points of $P$ imposes

$$\mathcal{C} = n \binom{m+1}{2}$$

(13)

constraints on $Q$.

The $(1, \varpi)$-weighted degree of monomial $\phi_a z^b$ is $\deg_{1, \varpi} \phi_a z^b = -v_{\varpi}(\phi_a) + \varpi b$, where $\varpi$ is determined by the code dimension $k$. Given two distinct monomials $\phi_a z^{b_1}$ and $\phi_a z^{b_2}$, we can arrange them in the following $(1, \varpi)$-revlex order. We claim $\varpi = 0$.

In GS decoding of an $(n, k)$ elliptic code, monomials are organized under the $(1, k)$-revlex order. Since $\varpi = 0$, we can arrange them in the following $(1, k)$-revlex order. We claim $\varpi = 0$.

Theorem 1 ([15]): Given the interpolation polynomial $Q$ and a polynomial $h$ in the form of (5), if

$$m(n - [\{i \mid h(P_i) \neq r_i, \forall i\}] > \deg_{1, k} Q,$$

(14)

then $Q(x, y, h) = 0$ or $(z - h) \mid Q$.

Proof: Substituting $h$ into (11) yields $Q(x, y, h) = \sum_{\mu, \nu \in \mathbb{N}} D^{(P_i, r_i)}(Q) \psi_{\mu, \nu}((h-r_i)^\nu)$. For point $(P_i, r_i)$ that satisfies $h(P_i) = r_i$, $\psi_{\mu, \nu}(Q(x, y, h)) = \min\{v_P(\psi_{\mu, \nu}) + v_P((h-r_i)^\nu) \mid D^{(P_i, r_i)}(Q) \neq 0\} \geq m$. Hence, $Q(x, y, h)$ has a zero of order at least $m(n - [\{i \mid h(P_i) \neq r_i, \forall i\}]$ over the $n$ interpolation points, i.e., $\sum_{i=0}^{n-1} v_P(Q(x, y, h)) \geq m(n - [\{i \mid h(P_i) \neq r_i, \forall i\}]$. Since $h$ is a polynomial in the form of (5), $\deg_{1, k} h = -v_{\varpi}(h) \leq k$ and $-v_{\varpi}(Q(x, y, z)) = \deg_{1, k} Q(x, y, z) \leq \deg_{1, k} Q$, the zero $Q(x, y, h)$ is greater than its pole order. As a result, $Q(x, y, h) = 0$, or alternately $(z - h) \mid Q$.

Therefore, if any monomial $f$ can be decoded, the GS algorithm corrects $[\{i \mid f(P_i) \neq r_i, \forall i\}]$ and its reduction need to be given. Consider an $F_q[x]$-module $\mathcal{I}$ of dimension $p$. Any basis of $\mathcal{I}$ can be represented as a matrix in $F_q[x]$, denoted as $\Xi$.

Definition 3: Let $\xi = (\xi_0(x), \xi_1(x), \ldots, \xi_{p-1}(x))$ denote a vector over $F_q[x]$, and $w = (w_0, w_1, \ldots, w_{p-1}) \in \mathbb{N}^p$, the $w$-weighted degree of $\xi$ is defined as

$$\deg_w(\xi) = \max\{\deg_{1, w} \xi_s(x) + w_s, \forall s\}.$$

(19)

The leading position of $\xi$ is

$$LP_w(\xi) = \max\{s \mid \deg_{1, w} \xi_s(x) + w_s = \deg_w(\xi)\}.$$

(20)

errors. Given an interpolation multiplicity $m$, let $l$ and $\tau$ denote the corresponding maximum decoding output list size and the error-correction capability, respectively. Note that $\deg_z Q \leq l$.

The following Theorem characterizes $l$ and $\tau$.

Theorem 2 ([21]): For an $(n, k)$ elliptic code, given an interpolation multiplicity $m$, the maximum decoding output list size

$$l = \left\lfloor \frac{nm(n + 1)}{k} + \frac{1}{4} - \frac{1}{2} \right\rfloor.$$

(16)

If $m(n - \tau) - kl \neq 1$, then the decoding can correct at most

$$\tau = n - \left\lfloor \frac{1}{m + 1} + \frac{(m + 1)n}{2(l + 1)} \right\rfloor - 1$$

(17)

errors. Otherwise, it can correct at most

$$\tau = n - \frac{1 + kl}{m}$$

(18)

errors.

Proof: Interpolating the $n$ points with a multiplicity of $m$ imposes $\mathcal{C}$ interpolation constraints. Polynomial $Q$ should contain at least $\mathcal{C} + 1$ coefficients so that the linear system will have a nonzero solution. Therefore,

$$l = \max \{t \mid \deg_z(t) \leq \mathcal{C}\}.$$

In GS decoding of an $(n, k)$ elliptic code, monomials are organized under the $(1, k)$-revlex order. Since $\deg_z(t) \neq 1$ and $\deg_{1, k} Q \neq 1$, $Q(x, y, f) = 0$. Hence, any monomials $\phi_a z^b$ of $Q$ should satisfy $\deg_{1, k} \phi_a z^b < m(n - \tau)$, and $\deg_{1, k} \phi_a z^b < m(n - \tau) - kb$. Since $b = 0, 1, \ldots, l$, when $m(n - \tau) - kl \neq 1$, $[\{\phi_a z^b \mid \deg_{1, k} \phi_a z^b < m(n - \tau)\}] = \sum_{b=0}^{l} m(n - \tau) - kb = 1 = m(l + 1)(n - \tau) - kl + l - 1$. Therefore, when

$$m(l + 1)(n - \tau) - kl + l - 1 > \mathcal{C},$$

the linear system has a nonzero solution. Solving the above inequality leads to (17). Otherwise, when $m(n - \tau) - kl = 1$, (18) can be reached.

C. Basis Reduction Algorithms

We solve the interpolation problem using the BR technique, which consists of module basis construction and its reduction. Therefore, some prerequisites on module basis representation and its reduction need to be given. Consider an $F_q[x]$-module $\mathcal{I}$ of dimension $p$. Any basis of $\mathcal{I}$ can be represented as a matrix in $F_q[x]$, denoted as $\Xi$.

Definition 3: Let $\xi = (\xi_0(x), \xi_1(x), \ldots, \xi_{p-1}(x))$ denote a vector over $F_q[x]$, and $w = (w_0, w_1, \ldots, w_{p-1}) \in \mathbb{N}^p$, the $w$-weighted degree of $\xi$ is defined as

$$\deg_w(\xi) = \max\{\deg_{1, w} \xi_s(x) + w_s, \forall s\}.$$

(19)

The leading position of $\xi$ is

$$LP_w(\xi) = \max\{s \mid \deg_{1, w} \xi_s(x) + w_s = \deg_w(\xi)\}.$$

(20)
and the leading term of $\xi$ is
\[ LT_\omega(\xi) = \xi LP_\omega(\xi)(x). \tag{21} \]

Coefficient of the leading monomial of $LT_\omega(\xi)$ is called its leading coefficient, denoted as $LC(LT_\omega(\xi))$.

**Definition 4:** Given a matrix $\Xi$ over $F_q[x]$, let $\Xi_t$ and $\Xi_{t,s}$ denote its row-$t$ and its entry of row-$t$ column-$s$, respectively, the $\omega$-weighted degree of $\Xi$ is
\[ \deg_\omega \Xi = \max \{ \deg_\omega \Xi_t, \forall t \}. \tag{22} \]

Note that in the un-weighted variants of the above definitions, $\deg(\xi)$, $LP(\xi)$, $LT(\xi)$ and $\deg \Xi$, respectively.

**Definition 5:** Given a square matrix $\Xi$ over $F_q[x]$, it is in the weak Popov form if and only if $LP(\Xi_t) \neq LP(\Xi_s)$, $\forall t \neq t'$.

Presenting the interpolation module basis as a square matrix in $F_q[x]$, the Gröbner basis is reached if it is reduced into the weak Popov form [25]. The desired interpolation polynomial $Q$ is the minimum candidate of the Gröbner basis. There exist several algorithms for reducing matrix $\Xi$ into the weak Popov form including the Lee-O’Sullivan algorithm [26], the MS algorithm [28], the Alekhnovich algorithm [29] and the GJV algorithm [30]. Their complexity mainly depend on $\deg \Xi$ and the orthogonality defect $\Delta(\Xi)$ that is defined as
\[ \Delta(\Xi) = \text{rowdeg}\Xi - \text{det}\Xi \leq \rho \deg \Xi, \]
where $\text{rowdeg}\Xi = \sum_{i=1}^{a_n} \deg \Xi_i$ and $\text{det}\Xi$ denotes the determinant of $\Xi$. Let $\Upsilon(u)$ denote the number of finite field arithmetic operations needed in multiplying two polynomials of degree at most $u$. For finite fields that support the fast Fourier transformation, $\Upsilon(u) = 18u \log_q u + O(u)$, while in general, $\Upsilon(u) = (18 + 72 \log_2 5)u \log_q u \log_q u + O(u \log_q u)$ [37]. Table I summarizes the complexity of the existing basis reduction techniques, where $O^\sim$ denotes the complexity characterization $O$ without considering the log factors, and $\pi (\pi \leq 3)$ denotes the exponent for multiplication of $F_q$ matrices. Table I shows the Alekhnovich and the GJV algorithms exhibit an asymptotically lower complexity than the other two algorithms. Note that normally $\rho \ll \Delta(\Xi)$ and $\rho \ll \deg \Xi$. However, they rely on the fast multiplication techniques which contribute to a large constant factor that is not reflected in the characterizations. This research has found out that the Lee-O’Sullivan and the MS algorithms are more efficient for handling codes of practical length. Therefore, we use the Lee-O’Sullivan algorithm for the basis reduction. Its complexity issue will be addressed again in Section V.

### III. THE BR INTERPOLATION

The BR interpolation consists of module basis construction and its reduction. The former constructs a basis of $F_q[x]$-module consisting of polynomials which satisfy the interpolation constraints. Gröbner basis of the module will be obtained by reducing this basis, where its minimum candidate is the desired polynomial $Q$.

### A. Prerequisites

Let $P = E(F_q) \setminus \{P_\infty\}$ denote the set of affine points on $E$. Let $A_0$ denote the set of $x$-coordinates of all elements in $P$, and $B_i = \{y \mid y^2 + a_1 x + a_3 y = x^3 + a_2 x^2 + a_4 x + a_6\}$ as the set of $y$-coordinates defined by $x_i$. Note that $|A_0| = n/2$.

If $P_i = -P_k$, $x_i = x_k$, $B_i = B_k$, and $|B_i| = 2$, $\forall i$.

**Theorem 3:** Let a divisor $G = \sum_{i=1}^{n-1} [P_i]$, $\text{div}(G) = G - n[P_\infty]$.

**Proof:** For each $\alpha \in A_0$, there exist two different affine points $P_i$ and $P_i'$ such that $\text{div}(x - \alpha) = [P_i] + [P_i'] - 2[P_\infty]$. Therefore, $\text{div}((\prod_{\alpha \in A_0} (x - \alpha)) = G - n[P_\infty]$.

The following Lagrange interpolation functions over $F_q[x]$ are introduced.

**Theorem 4:** Given $\Xi = (r_0, r_1, \ldots, r_{n-1}) \in \mathbb{F}_q^n$, let
\[ \kappa_\Xi = \sum_{i=0}^{n-1} r_i \mathcal{L}_i, \tag{24} \]
where
\[ \mathcal{L}_i = \prod_{\begin{array}{c} \alpha \in A_0 \setminus \{x_i\} \\
\beta \in B_i \end{array}} \frac{x - \alpha}{x_i - \alpha} \frac{y - \beta}{y_i - \beta}. \tag{25} \]

Note that $\kappa_\Xi \in \mathbb{R}$. It satisfies $\kappa_\Xi(P_i) = r_i$, $\kappa_\Xi(P_i') = 0$, $\forall i' \neq i$ and $\deg_{1,k} \kappa_\Xi \leq n + 1$. The complexity of computing $\kappa_\Xi$ is $O^\sim(n)$.

**Proof:** Since $|B_i| = 2$, $\deg \mathcal{L}_i < 2$, i.e., $\kappa_\Xi \in \mathbb{R}$. Substituting $P_i$ into $\mathcal{L}_i$ yields $\mathcal{L}_i(P_i) = 1$. For $\Xi \neq i$, $\mathcal{L}_i(P_i') = 0$. Hence, $\kappa_\Xi(P_i) = r_i$, and $\kappa_\Xi(P_i') = 0$, $\forall i' \neq i$. Since $\deg_{1,k} \mathcal{L}_i = n + 1$, $\deg_{1,k} \kappa_\Xi \leq n + 1$.

Let $P_i = (x_i, y_i)$ and $-P_i = (x_i, y_i^*)$, i.e., $B_i = \{y_i, y_i^*\}$. $\kappa_\Xi$ of (24) can be written as
\[ \kappa_\Xi = \sum_{i=0}^{n-1} \frac{r_i}{y_i - y_i^*} \prod_{\alpha \in A_0 \setminus \{x_i\}} \frac{x - \alpha}{x_i - \alpha} - \sum_{i=0}^{n-1} \frac{r_i y_i^*}{y_i - y_i^*} \prod_{\alpha \in A_0 \setminus \{x_i\}} \frac{x - \alpha}{x_i - \alpha}. \]

Since $\frac{1}{y_i - y_i^*}$ and $y_i^*$ are pre-computed, computing $\kappa_\Xi$ can be seen as two univariate interpolation problems for $\frac{1}{y_i - y_i^*}$ points. Using the fast interpolation algorithm of [37], computing $\kappa_\Xi$ exhibits a complexity of $O^\sim(n)$.

**Complexity for Computing a Weak Popov Form of $\Xi \in F_q[x]^{\rho \times \rho}$**
B. Basis Construction

Let \( I_\mathcal{P} \subset \mathbb{R}[z] \) denote a set of polynomials \( Q \) which have a zero of multiplicity \( m \) at the interpolation points of \( \mathcal{P} \). Let \( I_\mathcal{P} \) is an \( \mathbb{R} \)-module. Based on Theorems 3 and 4, for an interpolation point \((P_i, r_i)\), \( G(P_i) = 0 \) and \( r_i - K_z(P_i) = 0 \). Polynomials \( G \) and \( z - K_z \) interpolate all points of \( \mathcal{P} \).

To introduce the basis construction, the following Lemma is needed.

**Lemma 5:** Let \( Q = \sum_{j=0}^{m} Q_j z^j \in I_\mathcal{P} \) with \( \deg_z Q = \rho < m \), \( G^{m-\rho}Q \).

**Proof:** Since \( Q \in I_\mathcal{P} \), w.r.t. \((P_i, r_i)\), it can be written as \( Q = \sum_{\mu=0}^{m} \sum_{\nu=0}^{\rho} Q_{\mu\nu} L_i(\nu \cdot r_i)^\mu \). Since \( \deg_z Q = \rho < m \) and \( \nu \leq \rho \), \( Q_{\mu\nu} = \sum_{\mu=0}^{m-\rho} Q_{\mu\nu} L_i(\nu \cdot r_i)^\mu \), i.e., \( \Lambda^{m-\rho}Q \).

Following a similar manner to [12] and [26], the following module generators are introduced.

**Theorem 6:** \( I_\mathcal{P} \) is generated as an \( \mathbb{R} \)-module by the following \( l + 1 \) polynomials in \( \mathbb{R}[z] \):

\[
H^{(j)} = G^{m-j}(z - K_z)\rho \quad \text{if} \quad 0 \leq j \leq m, \quad (26)
\]

\[
H^{(j)} = z^{j-m}(z - K_z)^m \quad \text{if} \quad m < j \leq l. \quad (27)
\]

They are called the module generators.

**Proof:** Since both \( G \) and \( z - K_z \) interpolate all points of \( \mathcal{P} \), \( H^{(j)} \) has a zero of multiplicity at least \( m \) at the points, i.e., \( H^{(j)} \in I_\mathcal{P} \). Not that for polynomial \( H^{(i)} \), \( H^{(i)} = 1 \).

Given a polynomial \( Q \in I_\mathcal{P} \), there exists \( h_i = Q_i \) such that \( Q^{(i-1)} = Q - h_i H^{(i)} \).

Similarly, \( Q^{(m-1)} = Q - \sum_{j=0}^{m-1} h_j H^{(j)} \).

Therefore, \( Q^{(m-1)} = \sum_{j=0}^{m-1} h_j H^{(j)} \).

With the above module generators, the module basis can be generated as follows.

**Theorem 7:** \( I_\mathcal{P} \) is generated as an \( \mathbb{F}_q[x]\)-module by the following basis

\[
\mathcal{M}_\mathcal{P} = \{ M_t | M_t = y^{(t \mod 2)} H^{(t)}(\frac{x}{2}) \}, 0 \leq t \leq 2l + 1. \quad (28)
\]

**Proof:** Based on Theorem 6, for each \( Q \in I_\mathcal{P} \), there exist \( h_0, \ldots, h_l \in \mathbb{R} \) such that \( Q = \sum_{j=0}^{l} h_j H^{(j)} \).

Therefore, given \( \mathcal{P} \), polynomials \( G \) and \( K_z \) can be defined.

**Theorem 8:** Constructing the basis \( \mathcal{M}_\mathcal{P} \) of (28) exhibits a complexity of \( O^*(m^3n) \).

**Proof:** Given an \((n, k)\) elliptic code, \( G^j \) for \( j = 1, 2, \ldots, m \) can be computed offline, and we also know the complexity of computing \( K_z \) is \( O^*(n) \). Eq. (24) can be written as \( K_z = K_{\alpha}(x) + K_{\beta}(x)Y \), where \( \deg_x K_{\alpha}(x) < \frac{n}{2} \) for \( i = 0, 1 \). Therefore, computing \( K_z, K_{\alpha}, K_{\beta}, \ldots, K_{\beta} \) exhibits a complexity of \( O^*(m^3n) \). Also note that they need to be rationalized into \( \mathbb{R} \) of (3). Its complexity would be \( O(\alpha(m)) \). Subsequently, computing the module generators \( H^{(j)} \) has a complexity of \( O^*(m^3n) \).

C. Basis Reduction

**Basis:** \( \mathcal{M}_\mathcal{P} \) will be further reduced, yielding the Gröbner basis \( \mathcal{M}_\mathcal{P} \), that contains the interpolation polynomial \( Q \).

Since \( R[z] \) is a free module over \( \mathbb{F}_q[x] \) with a rank of \( 2(l + 1) \), it has a free basis of \( \{1, y, z, y^2, \ldots, y^l, y^{l+1}\} \). \( I_\mathcal{P} \) is a submodule of \( \mathbb{R}[z] \). For each \( Q \in I_\mathcal{P} \), it can be expressed as \( Q = Q^{(0)} + Q^{(1)}y + \cdots + Q^{(2l+1)}y^{l+1} \), where \( Q^{(0)}, Q^{(1)}, \ldots, Q^{(2l+1)} \in \mathbb{F}_q[x] \). They can also be written as

\[
Q = (Q^{(0)}, Q^{(1)}, \ldots, Q^{(2l+1)})(1, y, \ldots, y^{l+1})^T. \quad (29)
\]

Similarly, the basis polynomial can be written as \( M_t = (M_t^{(0)}, M_t^{(1)}, \ldots, M_t^{(2l+1)})(1, y, \ldots, y^{l+1})^T \). The basis \( \mathcal{M}_\mathcal{P} \) can be represented as a matrix \( V \) in \( \mathbb{F}_q[x] \) by letting

\[
V_t = (M_t^{(0)}, M_t^{(1)}, \ldots, M_t^{(2l+1)}), \quad (30)
\]

where \( V_t \) is a free basis of \( \{1, y, z, y^2, \ldots, y^l, y^{l+1}\} \). Therefore, \( M_t = V_t \cdot (1, y, \ldots, y^{l+1})^T \). Based on (eqs. (26)-(28)), it can be seen that \( V \) is a lower triangular matrix. By letting \( w_k = k \binom{x}{2} + 3(s \mod 2) \), we have \( \deg_{w_k} V_t = \deg_{w_k} M_t \).

The Lee-O’Sullivan basis reduction algorithm will be applied to reduce \( \mathcal{M}_\mathcal{P} \) into the desired Gröbner basis. For each row \( V_t \), \( \text{LP}_{w_k}(V_t) \) can be determined. Row operations of \( V \) will be performed until \( \text{LP}_{w_k}(V_t) = t \). Since \( M_0 = G^{m}y \) and \( M_1 = G^{m}y \), \( \text{LP}_{w_k}(V_0) = 0 \) and \( \text{LP}_{w_k}(V_1) = 1 \). The row operation can start from \( V_0 \). In general, if \( \text{LP}_{w_k}(V_t) = t \), \( V_t \) does not need to be modified. Row \( V_t+1 \) will be further processed. If \( \text{LP}_{w_k}(V_t) = t \) and \( t \neq t' \), we let \( u = \deg_{w_{t'}} \text{LP}_{w_{t'}}(V_t) \) and \( v = \text{LC}((\text{LT}_{w_k}(V_t)) \text{LC}((\text{LT}_{w_k}(V_t)))^{-1} \). If \( u > 0 \), \( V_t \) will be updated by

\[
V_t' = V_t - ux^n \cdot V_t. \quad (31)
\]

Otherwise, \( V_t' \) and \( V_t \) will be updated by

\[
V_t' = V_t \quad (32)
\]

and

\[
V_t' = V_t' - v \cdot \text{LP}_{w_{t'}}(V_t). \quad (33)
\]

Note that the update of \( V_t \) only involves the first \( t - 1 \) rows of \( V \), which does not change the leading position of those rows. Finally, the updated matrix \( V' \) satisfies \( \text{LP}_{w_k}(V') = t \), \( \forall t \). The updated polynomials can be further obtained by

\[
M_t' = V_t' \cdot (1, y, \ldots, y^{l+1})^T, \quad (34)
\]

which form the Gröbner basis \( \mathcal{M}_\mathcal{P} \) of \( I_\mathcal{P} \).

The minimum candidate of \( \mathcal{M}_\mathcal{P} \) is chosen as the interpolation polynomial \( Q \).
Algorithm 1 The BR Interpolation

Input: $\mathcal{L}$ and $m$;  
Output: $Q$;

1: Initialize $\mathcal{M}_P$ as in (26)-(28);
2: Represent $\mathcal{M}_P$ as matrix $\mathcal{V}$ over $\mathbb{F}_q[x]$ as in (30);
3: Reduce $\mathcal{V}$ into a weak Popov form matrix $\mathcal{V}'$ using Lee-O’Sullivan’s algorithm;
4: Demap the matrix $\mathcal{V}'$ to $\mathcal{M}_P$, as in (34);
5: Pick up the minimum candidate from $\mathcal{M}_P$ as $Q$.

Summarizing the above description, the BR interpolation algorithm for GS decoding of elliptic codes can be stated as follows.

The complexity and validity of the above interpolation algorithm is further characterized as the follows.

Theorem 9: Algorithm 1 is correct. Given basis $\mathcal{M}_P$, they can be presented as a matrix $\mathcal{V} \in \mathbb{F}_q[x]^{2l+1 \times (m+1)}$. The complexity of Algorithm 1 is $O(3m^2 n(n-k))$.

Proof: Based on Theorem 7, $\mathcal{M}_P$ generates the $\mathbb{F}_q[x]$ module $\mathcal{I}_P$. Therefore, $\mathcal{M}_P$ obtained by $\mathbb{F}_q[x]$ row operations is still a basis of $\mathcal{I}_P$. For $Q \in \mathcal{I}_P$, by (29), let $Q = (Q_1, \ldots, Q_{l+1})^T$, where $Q = (Q(1), Q(2), \ldots, Q(2l+1))$. Since the updated matrix $\mathcal{V}'$ satisfies $\text{LP}_w(\mathcal{V}') = t$, $\forall t$, there exists $t$ such that $\text{LP}_w Q = \text{LP}_w \mathcal{V}'$ and $\text{LT}_w \mathcal{V}' \mid \text{LT}_w Q$. Therefore, $\mathcal{M}_P$ is a Gröbner basis of $\mathcal{I}_P$, and the minimum polynomial of $\mathcal{I}_P$ is also the minimum element of $\mathcal{M}_P$.

Based on Theorem 8, complexity of constructing the basis $\mathcal{M}_P$ is $O(\delta n)$. Since $\deg_{\text{deg}_x} \mathcal{V} = n$ and $\deg_{\text{deg}_x} \mathcal{V}_w \leq n+1$, $\deg_{\text{deg}_x} \mathcal{V}_{2l+1} \leq m(n+1) + k(l-m) + 3$. If $t = 0, 2l+1, 2l+2, \ldots$, $\deg_{\text{deg}_x} \mathcal{V}_t = mn + 3t - 5$, $\deg_{\text{deg}_x} \mathcal{V}_{t,l} = m(n-m) + 2l + 3l$. Therefore, rowdeg $\mathcal{V} = \sum_{t=0}^{2l+1} \deg_{\text{deg}_x} \mathcal{V}_t = 2m^2n + (l-m)^2 + 3l$ and $\deg \mathcal{V} = \sum_{t=0}^{2l+1} \deg_{\text{deg}_x} \mathcal{V}_{t,l} = m^2n + l^2k + 3l$. Hence, $\deg \mathcal{V} \approx ml(n-k)$. Based on Table I, reducing $\mathcal{V}$ into a Gröbner basis requires at most $(2l+2) \deg_{\text{deg}_x} \mathcal{V} \Delta(\mathcal{V}) \approx 4 l^3 (m(n-k))(m(n+k-l)(m+n+k-l) - k)$ multiplications.

Based on Theorem 1, message polynomial $f$ can be further decoded by finding $z$-roots of $\mathcal{Q}$, i.e., $\mathcal{Q}(x,y,f) = 0$, which can be realized by the recursive search algorithm [35], [36]. Its complexity is quadratic in $n$. Although it has the same asymptotic complexity as the interpolation process, in practice, the root-finding complexity will be marginalized by interpolation. Based on the root-finding algorithm for RS codes [38], Alekhnovich provided a faster approach that yields a quasi-linear complexity in $n$ [29]. By using the concept of power series, Beelen and Høholdt further provided the root-finding algorithm for decoding AG codes [39]. Nielsen and Beelen also generalized Alekhnovich’s work to decode Hermitian codes [12], which yields a root-finding complexity that is sub-quadratic in $n$. They can be considered for decoding of elliptic codes. But the same asymptotic complexity (sub-quadratic in $n$) cannot be straightforwardly reached.

IV. THE RE-ENCODING TRANSFORMED INTERPOLATION

Re-encoding transformation helps reduce the BR interpolation complexity by reducing $x$-degree of the basis entries. The following introduces the transformation of interpolation points and the subsequent basis construction. The basis reduction remains unchanged.

A. Transform of the Interpolation Points

First, $\varepsilon$ interpolation points in $\mathcal{P}$ will be chosen as the re-encoding points for the transform. Let $\Gamma$ denote the index set of these re-encoding points, and $\Gamma^c$ denote the index set of the remaining points. With a received word $\mathcal{L} = (r_0, r_1, \ldots, r_{n-1})$, the re-encoding polynomial $\mathcal{K}_\Gamma \in \mathcal{L}(k[P])$ needs to be constructed for the transform.

Given $E$, let $\mathcal{P}_E = \{ P_i \mid i \in \Gamma \}$. For the points of $\mathcal{P}_E$, we further denote $\mathcal{A}_\Gamma = \{ P_i \mid i \in \Gamma \}$, $\mathcal{A}_\Gamma^c = \mathcal{A} \setminus \mathcal{A}_\Gamma$ and $\mathcal{B}(i) = \{ y \mid x_i, y \in \mathcal{P}_E \}$.

The re-encoding polynomial $\mathcal{K}_\Gamma$ can be defined as follows.

Theorem 10: Let

$$\mathcal{K}_\Gamma = \sum_{i \in \Gamma} r_i \mathcal{L}_{i}^{(i)}$$

where

$$\mathcal{L}_{i}^{(i)} = \prod_{\alpha \in \mathcal{A}_\Gamma \setminus \{ x_i \}} \frac{x - \alpha}{x_i - \alpha} \prod_{\beta \in \mathcal{B}(i) \setminus \{ y \}} \frac{y - \beta}{y_i - \beta}. \quad \text{(36)}$$

It satisfies $\mathcal{K}_\Gamma(P_i) = r_i$, $\forall i \in \Gamma$. Furthermore, let $\sigma = \{ i \mid \mathcal{B}(i) = \{ y \}, \forall y \in \mathcal{P}_E \}$; $\deg_{\text{deg}_x} \mathcal{K}_\Gamma = \sigma + \epsilon + 1$.

Proof: Eq. (36) ensures $\mathcal{L}_{i}^{(i)}(P_i) = 1$, and $\mathcal{L}_{i}^{(i)}(P_j) = 0$, $\forall P_j \neq P_i$ and $i \in \Gamma$. Therefore, $\mathcal{K}_\Gamma(P_i) = r_i$, $\forall i \in \Gamma$. If $\mathcal{B}(i) = 1$, $\deg_{\text{deg}_x} \mathcal{L}_{i}^{(i)} = \epsilon + \sigma - 2$. Otherwise, $\deg_{\text{deg}_x} \mathcal{L}_{i}^{(i)} = \epsilon + \sigma + 1$. Therefore, $\deg_{\text{deg}_x} \mathcal{K}_\Gamma = \epsilon + \sigma + 1$.

With the re-encoding polynomial, a new codeword can be generated by

$$\mathcal{L}' = (\mathcal{K}_\Gamma(P_0), \mathcal{K}_\Gamma(P_1), \ldots, \mathcal{K}_\Gamma(P_{n-1})) = (c_0', c_1', \ldots, c_{n-1}') \quad \text{(37)}$$

The received word $\mathcal{L} = (r_0, r_1, \ldots, r_{n-1})$ can therefore be transformed by

$$\mathcal{L}' = \mathcal{L} - \mathcal{L}' \quad \text{(38)}$$

where $r_i' = r_i - c_i'$. To simplify the description of the re-encoding transformed interpolation, the following encoding point rearrangement is needed.

Proposition 11: The evaluation encoding order of (6) is rearranged such that the affine points with the same $x$-coordinate are adjacent to each other.

Therefore, without loss of generality, the first $\varepsilon$ interpolation points are chosen as the re-encoding points, i.e., $\Gamma = \{ 0, 1, \ldots, \varepsilon - 1 \}$ and $\Gamma^c = \{ \varepsilon, \varepsilon + 1, \ldots, n - 1 \}$. Based on (38), the transformed received word becomes

$$r_i' = (0, \ldots, 0, r_x', r_{x+1}' , \ldots, r_{n-1}') \quad \text{(39)}$$
Consequently, the set of interpolation points $\mathbf{P}$ is transformed into

$$
\mathbf{P'} = \{(P_0, 0), \ldots, (P_{r'-1}, 0), (P_r, r'_r), \ldots, (P_{r'-1}, r'_{r'-1})\}.
$$

This enables the basis polynomials yield a common factor, which can be removed before the basis reduction. Note that $K_{\Gamma} \in \mathbb{Z}[k[P_\infty]]$, i.e., $\varepsilon + \sigma + 1 \leq k$, which limits the number of re-encoding points. In order to maximize the number of points in $\mathbf{P'}$ with coordinate being zero, $\sigma$ should be as small as possible.

**Corollary 12:** Given $C_E(G, k[P_\infty])$ and $\sigma \leq 1$, if $k$ is odd, $\varepsilon = k - 1$; otherwise, $\varepsilon = k - 2$.

**Proof:** Recalling Theorem 10, if $\varepsilon$ is even, i.e., $\sigma = 0$, $\deg_{1,k} K_{\Gamma} = \varepsilon + 1$. Otherwise, $\deg_{1,k} K_{\Gamma} = \varepsilon + 2$. To construct an $(n, k)$ elliptic code, we need to maintain $\deg_{1,k} K_{\Gamma} \leq k$. Hence, if $k$ is odd, $\varepsilon = k - 1$. Otherwise, $\varepsilon = k - 2$.

**B. Basis Construction**

Let $\mathcal{I}_{\mathbf{P'}} \subset \mathcal{R}[z]$ denote a set of $Q$ which have a zero of multiplicity $m$ at the transformed interpolation points in $\mathbf{P'}$. The following theorem describes the relationship between $\mathcal{I}_{\mathbf{P'}}$ and $\mathcal{I}_{\mathbf{P}}$.

**Theorem 13:** $Q$ is the interpolation polynomial in $\mathcal{I}_{\mathbf{P}}$ if and only if $Q = Q(x, y, z + K_{\Gamma})$ is also one in $\mathcal{I}_{\mathbf{P'}}$.

**Proof:** Based on Theorem 7, if $Q \in \mathcal{I}_{\mathbf{P'}}$, $Q(x, y, z + K_{\Gamma}) = \sum_{j=0}^{l} \sum_{s=0}^{m} h_j^{(s)}(y)\mathcal{H}(j)$, where $h_j^{(s)} \in \mathcal{P}_{[0]}$ and $\mathcal{H}(j) = \mathcal{H}(j)(x, y, z + K_{\Gamma})$. Based on eqs. (26) and (27),

$$
\mathcal{H}(j) = G^{m-j}(z + K_{\Gamma} - K_{\Gamma}^m), \quad \mathcal{H}(j) = (z + K_{\Gamma})^{m-j}(z + K_{\Gamma} - K_{\Gamma}^m), \quad \text{if } m < j < l.
$$

Since $K_{\Gamma}(P_i) - K_{\Gamma}(P_i) = r_i - c_i = r'_i$, $\mathcal{H}(j)$ has a zero of multiplicity $m$ at the transformed interpolation points, i.e., $\mathcal{H}(j) \in \mathcal{I}_{\mathbf{P'}}$. Therefore, $Q \in \mathcal{I}_{\mathbf{P'}}$. If $Q \in \mathcal{I}_{\mathbf{P'}}$, $Q \in \mathcal{I}_{\mathbf{P}}$.

Since $\deg_{1,k} K_{\Gamma} \leq k$, $\deg_{1,k} z = \deg_{1,k}(z + K_{\Gamma}) = k$, and $\deg_{1,k} Q = \deg_{1,k} Q$. If $Q$ is the interpolation polynomial in $\mathcal{I}_{\mathbf{P}}$, $Q \in \mathcal{I}_{\mathbf{P'}}$. If there exists $Q' \in \mathcal{I}_{\mathbf{P'}}$ which satisfies $\deg_{1,k} Q' < \deg_{1,k} Q$. $Q' = Q(x, y, z + K_{\Gamma}) \in \mathcal{I}_{\mathbf{P}}$ and it satisfies $\deg_{1,k} Q' = \deg_{1,k} Q$. This leads to $\deg_{1,k} Q' < \deg_{1,k} Q$. It contradicts $Q$ being the minimum polynomial of $\mathcal{I}_{\mathbf{P}}$. Therefore, $Q$ is the minimum interpolation polynomial in $\mathcal{I}_{\mathbf{P'}}$, and vice versa.

Therefore, the interpolation polynomial $Q$ can be obtained by $Q = Q(x, y, z - K_{\Gamma})$. To describe the basis construction in the case of re-encoding transform, the following notations are needed. Note that polynomial $G$ of (23) can be factorized into

$$
G = G_{\Gamma}G_{\Gamma^e},
$$

where

$$
G_{\Gamma} = \prod_{\alpha \in \mathcal{I}_{\mathbf{P}}} (x - \alpha)
$$

and

$$
G_{\Gamma^e} = \prod_{\alpha \in \mathcal{I}_{\mathbf{P'}}} (x - \alpha).
$$

Based on $\mathcal{I}_F$ (eq. (39)) and $\mathbf{P'}$ (eq. (40)), $K_{\Gamma^e}$ of (24) can be defined as

$$
K_{\Gamma^e} = \sum_{i=0}^{L} L_i + \sum_{i=1}^{\varepsilon} r'_i L_i
$$

where

$$
G_{\Gamma} = \prod_{i=0}^{\varepsilon} G_{\Gamma}(x_i) \prod_{\alpha \in \mathcal{I}_{\mathbf{P'}} \setminus \{x_i\}} \frac{x - \alpha}{x_i - \alpha} \prod_{\beta \in \mathcal{I}_{\mathbf{P'}} \setminus \{y_i\}} \frac{y - \beta}{y_i - \beta}.
$$

Therefore, $G_{\Gamma}$ becomes the GCD for both $G$ and $K_{\Gamma^e}$. Let us rewrite $K_{\Gamma^e}$ as

$$
K_{\Gamma^e} = G_{\Gamma}K_{\Gamma^e},
$$

where

$$
K_{\Gamma^e} = \sum_{i=\varepsilon}^{\varepsilon} r'_ig_{\Gamma^e}(i),
$$

and

$$
G_{\Gamma^e} = \prod_{\alpha \in \mathcal{I}_{\mathbf{P'}} \setminus \{x_i\}} \frac{x - \alpha}{x_i - \alpha} \prod_{\beta \in \mathcal{I}_{\mathbf{P'}} \setminus \{y_i\}} \frac{y - \beta}{y_i - \beta}.
$$

For the transformed interpolation points of $\mathbf{P'}$, its subset $\{(P_i, r'_i) | i \in \mathcal{I}_{\mathbf{P'}}\}$ can be further transformed into

$$
\mathbf{P} = \{(P_i, r'_i), \ldots, (P_{r'-1}, r'_{r'-1})\}.
$$

Note that for $(P_i, r'_i)$ where $i \in \mathcal{I}_{\mathbf{P'}}$, $r'_i = (P_i, r'_i)$. Similarly, let $\mathcal{I}_{\mathbf{P'}} \subset \mathcal{R}[z]$ denote a set of some $Q^*$ which have a zero of multiplicity $m$ at the points of $\mathbf{P'}$. The following Lemma first reveals the property of the polynomials in $\mathcal{I}_{\mathbf{P'}}$.

**Lemma 14:** If $Q \in \mathcal{I}_{\mathbf{P'}}$, $G_{\Gamma} Q(x, y, zG_{\Gamma})$.

**Proof:** Based on Theorem 6, $Q$ can be written as $Q = \sum_{j=0}^{m} j \mathcal{H}(j)$, which can be further elaborated as

$$
Q = \sum_{j=0}^{m} j \mathcal{H}(j) + \sum_{j=m+1}^{l} j \mathcal{H}(j) + \sum_{j=m+1}^{l} j \mathcal{H}(j) = \sum_{j=0}^{m} j \mathcal{H}(j) + \sum_{j=m+1}^{l} j \mathcal{H}(j) + \sum_{j=m+1}^{l} j \mathcal{H}(j).
$$

Therefore,

$$
Q(x, y, zG_{\Gamma}) = G_{\Gamma}^{m} \sum_{j=0}^{m} j \mathcal{H}(j) + \sum_{j=m+1}^{l} j \mathcal{H}(j) + \sum_{j=m+1}^{l} j \mathcal{H}(j).
$$

Thus, $G_{\Gamma}^{m} | Q(x, y, zG_{\Gamma})$.

Armed with the above lemma, the following bijective mapping between the polynomials of \( I_P \) and those of \( I_{P'} \) can be established

\[
\Psi : I_{P'} \to I_P.
\]

\[
Q(x, y, z) \mapsto Q^* (x, y, z) = G_{\Gamma'}^{-m} Q(x, y, z G_{\Gamma'}), \tag{50}
\]

where \( \Psi \) is an \( F_q[x] \)-module isomorphism between \( I_{P'} \) and \( I_P \). Therefore, \( I_{P'} \) can be generated as an \( F_q[x] \)-module by the following 2l + 2 polynomials

\[
M_{P'} = \{ M^*_i \mid M^*_i = y^{(t \mod 2)} H_i^{(\frac{1}{2})}, 0 \leq t \leq 2l + 1 \}, \tag{51}
\]

where

\[
H_i^{(j)} = G_{\Gamma'}^{-m-j} (z - K_{\Gamma'}), \quad 0 \leq j \leq m, \tag{52}
\]

\[
H_i^{(j)} = (G_{\Gamma'} z)^{-m} (z - K_{\Gamma'}), \quad m < j \leq l. \tag{53}
\]

Polynomials \( M^*_i \) of (51) have a zero of multiplicity \( m \) at the points of \( P^* \). Comparing with the polynomials of \( M_{P'} \) (see eqs. (26)-(28)), polynomials of \( M_{P'} \) have lower \( x \)-degrees. This can reduce the basis reduction complexity. If \( Q^* \in I_{P'} \), it can be written as an \( F_q[x] \)-linear combination of the above polynomials, i.e.,

\[
Q^* = \sum_{t=0}^{2l+1} h_i M^*_i, \tag{54}
\]

where \( h_i \in F_q[x] \). We further prove that constructing \( I_{P'} \) will be sufficient to obtain the interpolation polynomial \( Q \).

**Lemma 15:** If \( Q \in I_{P'} \), \( \deg_{1, k} Q = \deg_{1, \infty} G_{\Gamma'} + \deg_{1, \infty} Q^* \), where \( \infty = 1 \) if \( k \) is odd, otherwise, \( \infty = 2 \).

**Proof:** Based on eq. (50), we know \( Q = G_{\Gamma'}^{-m} Q^* (x, y, z G_{\Gamma'}) \).

Let \( Q^* = \sum_{j=0}^{2l} Q^*_j z^j \), where \( Q^*_j \in R \), it follows that

\[
\deg_{1, k} Q = \deg_{1, k} G_{\Gamma'} + \deg_{1, k} Q^* \left( x, y, z \frac{z}{G_{\Gamma'}} \right) = \deg_{1, k} G_{\Gamma'} + \deg_{1, k} \sum_{j=0}^{2l} Q^*_j \left( \frac{z}{G_{\Gamma'}} \right)^j = \deg_{1, k} G_{\Gamma'} + \max_{0 \leq j \leq 2l} \{ \deg_{1, k} Q^*_j \} + j(k - \deg_{1, k} G_{\Gamma'}). \]

Therefore, \( \deg_{1, k} Q = \deg_{1, \infty} G_{\Gamma'} + \deg_{1, \infty} Q^* \), where \( \infty = k - \deg_{1, k} G_{\Gamma'} \). Based on Corollary 12 and (42), if \( k \) is odd, \( \deg_{1, k} G_{\Gamma'} = k - 1 \); otherwise, \( \deg_{1, k} G_{\Gamma'} = k - 2 \).

Since \( M^*_i = M^*_i (0), M^*_i (1), \ldots, M^*_i (2l+1) y^s \), polynomials of \( M_{P'} \) can be represented as a matrix \( V^* \in F_q[x]^{2l(t+1) 	imes 2l(t+1)} \) by letting

\[
V^*_i = \left( M^*_i (0), M^*_i (1), \ldots, M^*_i (2l+1) \right). \tag{55}
\]

Hence, \( M^*_i = V^*_i (1, y, \ldots, y^s)^T \) and \( V^*_i x = M^*_i (x) \). Based on Lemma 15, if \( k \) is odd, \( \infty = 1, w_i = \left( \frac{x}{y} \right)^i + 3(s \mod 2) \) for \( s = 0, 1, \ldots, 2l + 1 \) and \( \deg V^*_i = \deg_{1, k} M^*_i \). Otherwise, \( \infty = 2, w_i = 2 \left( \frac{x}{y} \right)^i + 3(s \mod 2) \) and \( \deg V^*_i = \deg_{1, 2} M^*_i \). We can further apply the row reduction described in Section III.C to reduce \( M_{P'} \) into a Gröbner basis w.r.t. the \((1, \infty)\)-revlex order, denoted as \( M_{P'} \).

**Theorem 16:** Given \( Q^* \) as the minimum polynomial in \( I_{P'} \), the interpolation polynomial \( Q \) can be obtained by

\[
Q = G_{\Gamma'}^{-m} Q^* \left( x, y, z - \frac{K_{\Gamma'}}{G_{\Gamma'}} \right). \tag{56}
\]

**Proof:** Based on Theorem 13, if \( Q \) is the interpolation polynomial in \( I_{P'} \), \( Q = Q(x, y, z - K_{\Gamma'}) \) will be the interpolation polynomial in \( I_{P'} \). Therefore, we only need to prove that \( Q = G_{\Gamma'}^{-m} Q^* (x, y, z G_{\Gamma'}) \). Based on Lemma 15, \( \deg_{1, \infty} G_{\Gamma'} \leq \deg_{1, \infty} Q^{*'} < \deg_{1, \infty} G_{\Gamma'} + \deg_{1, \infty} Q^* \), i.e., \( \deg_{1, \infty} Q^{*'} < \deg_{1, \infty} Q^* \), which contradicts \( Q^* \) being the minimum polynomial in \( I_{P'} \).

Therefore, after constructing \( M_{P'} \), we can first obtain \( Q^* \) by Lee-O’Sullivan’s algorithm that was introduced in Section III.C. Based on (50), the interpolation polynomial \( Q \) can be further obtained by

\[
Q = G_{\Gamma'}^{-m} Q^* \left( x, y, z \frac{z}{G_{\Gamma'}} \right), \tag{57}
\]

which interpolates the interpolation points of (40) with a multiplicity of \( m \). The z-roots \( f' \) of \( Q \) can be further determined. Estimation of the intended message polynomial \( f \) can be further obtained by

\[
f = f' + K_{\Gamma'}. \tag{58}
\]

Summarizing the above description, the above re-encoding transformed BR interpolation algorithm is stated as follows.

**Algorithm 2** The ReT BR Interpolation

**Input:** \( t \) and \( m \);

**Output:** \( Q \):

1. Transform the set of interpolation points of \( P \) into \( P' \) as in (37)-(40);
2. Obtain subset \( P^* \) of (48);
3. Initialize \( M_{P'} \) as in (51)-(53);
4. Represent \( M_{P'} \) as matrix \( V^* \) over \( F_q[x] \) as in (55);
5. Reduce \( V^* \) into a weak Popov form matrix \( V^{*'} \) using Lee-O’Sullivan’s algorithm;
6. Demap the matrix \( V^{*'} \) as \( M_{P'} \) as in (34);
7. Pick up the minimum candidate from \( M_{P'} \), as \( Q^* \);
8. Construct \( Q \) as in (57).

Based on Table I, the following Theorem shows the correctness and characterizes the complexity of Algorithm 2.

**Theorem 17:** Algorithm 2 is correct. Given basis \( M_{P'} \), it can be presented as a matrix \( V^* \in F_q[x]^{2l(t+1) 	imes 2l(t+1)} \). The complexity of Algorithm 2 is \( O(l^3 m^2 (n - k)^2) \).

**Proof:** Based on eqs. (50) and (51), \( M_{P'} \) is a basis of \( I_{P'} \). By using Lee-O’Sullivan’s algorithm, \( M_{P'} \) can be reduced into a Gröbner basis of \( I_{P'} \) w.r.t. the \((1, \infty)\)-revlex order. Based on Theorem 16 and (57), \( Q \) is a minimum polynomial of module \( I_{P'} \). Therefore, by determining the z-roots \( f' \) of \( Q \), the intended message polynomial \( f \) can be further obtained. Therefore, Algorithm 2 is correct.
TABLE II

<table>

</tbody>
</table>

For an $(n,k)$ elliptic code, based on Theorem 4, the reencoding polynomial $K_{tr}$ of (35) can be computed with a complexity of $O^\sim(n)$. Obtaining the interpolation points of (48) requires $O^\sim(n)$ field operations. Since deg$_{1,k}K_{tr} \leq n-\varepsilon+1$, computing $K_{tr}$ requires $O^\sim(n-\varepsilon)$ field operations. Therefore, computing $V_t^{(1)}$ of (52) and (53) requires $O^\sim(m^2(n-\varepsilon))$ and $O^\sim(m^2(l-m)n)$ field operations, respectively. Hence, the complexity of the basis construction is $O^\sim(m^2n^2)$. 

Based on (51) and (55), if $0 \leq t \leq 2m+1$, deg $V_t^\pi = m(n-\varepsilon) + \lceil \frac{\varepsilon}{2} \rceil (1-\varepsilon) + w_t$ and deg $V_{t,t}^\pi = (n-\varepsilon)(m-\lceil \frac{\varepsilon}{2} \rceil) + w_t$. If $2m+1 < t < 2l+2$, deg $V_{t,t}^\pi = m(n-2e-\varepsilon) + \varepsilon \lceil \frac{\varepsilon}{2} \rceil + w_t$ and deg $V_{t,t}^\pi = \varepsilon \lceil \frac{\varepsilon}{2} \rceil - m + w_t$. Therefore, deg $V_{t,t}^\pi \leq m(n-\varepsilon) + (l-m)(\varepsilon + \varepsilon) + 3$ and $\Delta(V_{t,t}^\pi) < 2ml(n-k)$. Reducing $V_{t,t}^\pi$ into a Gröbner basis requires at most $(2l+2)^2$ deg $\sum_i V_i^\pi \Delta(V_{t,t}^\pi) = 8l^3m(n-k) (m(n-k) + l(l-m))$ field operations. Moreover, restoring the interpolation polynomial as in (57) requires $O^\sim(lmn)$ field operations. Therefore, the complexity of Algorithm 2 can be characterized as $O(l^3(m^2(n-k)^2))$. 

In comparison with Theorems 8 and 9, it can be seen that the ReT helps reduce both of the basis construction and reduction complexity by a factor of $\frac{1}{\varepsilon}$. Therefore, this reduction will be more effective for high rate codes.

V. COMPLEXITY COMPARISON

We will further investigate the complexity of the basis reduction process using different approaches including the Lee-O’Sullivan algorithm [26], the MS algorithm [28], the Alekhnovich algorithm [29] and the GJV algorithm [30]. This analysis will reveal that the Lee-O’Sullivan algorithm remains the most efficient for decoding codes of practical length.

Given a matrix $V$ as in (30), different from Lee-O’Sullivan’s algorithm, the following mapping $\Phi_{\pi}$ is needed before the other three algorithms are used to reduce $V$ into the weak Popov form. Define the mapping $\Phi_{\pi}$ [12]: $F_q[x]^{2(l+1)} \rightarrow F_q[x]^{2(l+1)}$

$$V_t \mapsto V_t = (x^{w_0}M_t^{(0)}(x), x^{w_1}M_t^{(1)}(x), \ldots, x^{w_{2l+1}}M_t^{(2l+1)}(x)),$$

(59)

where $w_0, w_1, \ldots, w_{2l+1}$ and $w_x = \left[ \frac{k}{2} + 3(s \mod 2) \right]$. Therefore, matrix $V_{t,t}$ will be reduced. We now look into the complexity of the other three basis reduction algorithms under the decoding paradigm without the ReT.

**Theorem 18**: Given a matrix $V \in F_q[x]^{2(l+1)×2(l+1)}$, the complexity of reducing $V$ into the weak Popov form is summarized in Table II.

**Proof**: Based on (59), we know deg $V_t \leq \deg x$ deg $V_{2l+1,2l-2m} \leq \frac{m}{2} + \frac{k(l-m)}{2}$. If $0 \leq t \leq 2m+1$, deg $V_t \approx \frac{m}{2}$ and deg $V_{t,t} \approx \frac{m}{2} \left( \frac{m}{2} - \frac{t}{2} \right) + w_t$. If $2m+2 < t \leq 2l+1$, deg $V_t \approx \frac{m}{2} + \frac{k(l-m)}{2}$ and deg $V_{t,t} = w_t$. Therefore, rowdeg $V = \sum_{t=0}^{2l+1} \deg V_{t,t} \approx lmn + \frac{k}{2}(l-m)^2$ and deg $\det V = \sum_{t=0}^{2l+1} \deg V_{t,t} \approx \frac{m^2}{2} + \frac{k^2}{2}$. Hence, $\Delta(V) \approx ml(n-k)$. Based on the characterizations of Table I, the complexity characterizations in $l, m$ and $n$ for the Lee-O’Sullivan (and MS) algorithm, the Alekhnovich algorithm and the GJV algorithm are given in (60), (V), and (V), respectively. Omitting the log factors, their complexity characterizations in $O^\sim$ are further summarized in Table II.

$$2l^2mn(lm(n-k) + 2l),$$

(60)

$$18 + 72\log_2(2)/l^2 \approx \log(lmn) \log(mn) \log(mn),$$

(61)

$$18 + 72\log_2(2)/l^2 \approx mn \log(mn) \log(mn) \log(mn).$$

(62)

Since $\pi \leq 3$, Theorem 18 shows that the Alekhnovich and the GJV algorithms have lower asymptotically complexity. However, by carefully investigating the expressions of (60)-(V), we know that for practical $l, m$, and $n$, the Lee-O’Sullivan and the MS algorithms would yield a lower complexity. Note that the running times of the MS and the Alekhnovich algorithms in Magma have been examined in [31], which also showed the former has a smaller running time when $n$ is less than 3000.

VI. SIMULATION RESULTS

GS decoding of elliptic codes using the proposed BR interpolation have been simulated using C programming language. It is measured over the additive white Gaussian noise (AWGN) channel using BPSK. The decoding performances are presented as a function of the signal-to-noise ratio (SNR) which is defined as $E_b/N_0$, where $E_b$ and $N_0$ are the transmitted energy per information bit and the noise power density, respectively. For the BPSK modulated transmission, codeword symbols are firstly converted into binary representations, and 0 and 1 are mapped to the BPSK symbols of $(1,0)$ and $(-1,0)$, respectively. The decoding complexity is measured as the number of finite field arithmetic operations needed in decoding a codeword. The elliptic codes are compared with similar rate RS codes that are defined over the same finite field.

Figs. 1-3 show the frame error rate (FER) performance of the $(80,27)$, the $(80,39)$ and the $(288,163)$ elliptic codes, respectively. Our results show that with the same interpolation multiplicity $m$, elliptic codes can outperform their RS counterparts. Note that for all the codes, we choose the minimum $m$ that yields the corresponding error-correction capability. The decoding parameters are defined in Theorem 2. Over the same finite field, elliptic codes are longer. They inherit a greater error-correction capability, yielding a better decoding performance. It is interesting to point out that this also enables elliptic codes achieve a similar performance as RS codes with a smaller decoding complexity. E.g., Fig.1 shows that decoding the $(80,27)$ elliptic code with $m = 4$ performs similarly as decoding the $(63,21)$ RS code with $m = 5$. 

Authorized licensed use limited to: SUN YAT-SEN UNIVERSITY. Downloaded on October 21, 2021 at 02:57:43 UTC from IEEE Xplore. Restrictions apply.
The BR interpolation complexity is $1.16 \times 10^7$ for the elliptic code, and $1.20 \times 10^7$ for the RS code. If using Kötter’s interpolation, the complexity will be $1.65 \times 10^7$ for the elliptic code, and $2.72 \times 10^7$ for the RS code. A similar phenomenon can also be observed in Figs. 2 and 3. They demonstrate that elliptic codes can be considered to replace RS codes for better performance. Note that the optimal GS decoding performances are obtained by assuming the algorithm can decode at most $\tau_{GS}$ errors, where $\tau_{GS}$ was defined by eq. (15) for elliptic codes. For RS codes, $\tau_{GS} = n - \left\lceil \sqrt{n(k-1)} \right\rceil - 1$.

The proof of Theorem 9 shows that the basis reduction dominates the interpolation complexity, and its complexity reduces as the code rate increases. Tables III-IV show the numerical results of the interpolation complexity in decoding the (80, 27) and the (80, 39) elliptic codes, respectively. Our numerical results validate the characterization of Theorem 9.

With the same decoding parameters, e.g., $m = 2$ and $l = 3$, the BR interpolation exhibits a smaller complexity for the (80, 39) elliptic code. Note that the complexity of Kötter’s interpolation is $O\left(lm^4 n^2 \right)$, which exhibits the same asymptotic behavior as the BR interpolation. The ratio of the complexity of the two interpolation approaches is

$$\left( \frac{lm}{m+n} \right)^2 (1 - \frac{k}{n})$$

Since $m \leq l$, their comparison depends on the interplay between $\frac{m}{l}$ and $\frac{k}{n}$. Our numerical results show in practice, the BR interpolation has a smaller complexity than Kötter’s interpolation, with more significant reduction realized for the higher rate codes.

Tables V-VI show the numerical results of the BR interpolation assisted by the ReT. Pairing Tables III and V, IV and VI, the complexity reduction factor of $\frac{k}{n}$ can be observed. Note that with the ReT, Kötter’s interpolation exhibits a complexity of $O\left(lm^4 n(n-k) \right)$. Therefore, complexity of the BR interpolation and Kötter’s interpolation still exhibit a ratio of $\left( \frac{m}{l} \right)^2 (1 - \frac{k}{n})$. Our numerical results also show that for the
elliptic codes, the BR interpolation has a complexity advantage over Kötter’s interpolation by at most an order of magnitude.

VII. CONCLUSION

This paper has proposed the GS algorithm for decoding elliptic codes using the module basis reduction interpolation. The Lagrange interpolation function over the elliptic function fields has been proposed for constructing the module. A basis of the module containing polynomials that satisfy all the interpolation and degree constraints has also been defined. This basis can be further reduced by the Lee-O’Sullivan algorithm, resulting in the desired Gröbner basis that contains the interpolation polynomial $Q$. The re-encoding transform has been further introduced to reduce the degree of module basis entries, yielding a basis isomorphism. Its reduction exhibits a smaller complexity. This research has further shown the BR interpolation yields a complexity of $O(l^3 m^2(n-k))$. Assisted by the re-encoding transform, this complexity can be reduced to $O(l^3 m^2 (n-k)^2)$. They both show the interpolation technique will have a smaller complexity for high rate codes. Furthermore, we have analyzed the complexity of using the Alekhnovich and the GJV algorithms for the basis reduction process. They show a complexity of $O(\sim(l^{1+1/m}m)$ and $O(\sim(l^2mn))$, respectively. We have also demonstrated that for codes of practical length, the Lee-O’Sullivan and the MS algorithms will be more efficient. Finally, the BR interpolation’s complexity advantage over Kötter’s interpolation has also been demonstrated. Our simulation results have also demonstrated that elliptic codes can outperform the similar rate RS codes defined over the same finite field.
